

TMA4315: Project 2

jototlan@stud.ntnu.no (10018), martigtu@stud.ntnu.no (10037)

Problem 1

```
mammals <- read.table(  
  "https://www.math.ntnu.no/~jarlet/statmod/mammals.dat",  
  header=T)
```

a)

```
plot(log(mammals$body), log(mammals$brain)) # Seems pretty linear.
```

A log-log plot of the brain mass against body mass seems to reveal a linear trend. We thus fit the following model:

```
mod0 <- lm(log(brain) ~ log(body), data = mammals)  
summary(mod0)
```

```
##  
## Call:  
## lm(formula = log(brain) ~ log(body), data = mammals)  
##  
## Residuals:  
##      Min       1Q   Median       3Q      Max
```

```
## -1.71550 -0.49228 -0.06162  0.43597  1.94829
##
## Coefficients:
##             Estimate Std. Error t value Pr(>|t|)
## (Intercept)  2.13479    0.09604   22.23  <2e-16 ***
## log(body)    0.75169    0.02846   26.41  <2e-16 ***

```

Let $\hat{\beta} = [\hat{\beta}_0, \hat{\beta}_1, \hat{\beta}_2]^T$ be the coefficient estimates given in the summary above. Then the estimated effect on brain mass from being a human is $\hat{\beta}_2 \approx 2.0069072$. Since we have used a log-transform on both the brain mass and body mass, humans will according to the model be larger by a factor of $e^{\hat{\beta}_2} = 7.4402704$.

We use the notation $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ to represent the linear model. Here, \mathbf{X} is the $n \times p$ design matrix, where n is the number of observations and p is the number of parameters used in the model. As usual, $\boldsymbol{\varepsilon} \sim \mathcal{N}(\mathbf{0}, \sigma^2 \mathbf{I}_n)$. This (along with the other usual assumptions [how much detail is required here??](#)) gives the well known result:

$$\hat{\boldsymbol{\beta}} \sim \mathcal{N}(\boldsymbol{\beta}, \sigma^2 (\mathbf{X}^T \mathbf{X})^{-1}).$$

Now we want to perform the hypothesis test

$$H_0 : \beta_2 = 0 \quad \text{vs.} \quad H_1 : \beta_2 > 0.$$

Under H_0 , we obtain that (we also index from 0 in the design matrix)

$$\frac{\hat{\beta}_2}{\sigma \sqrt{(X^T X)_{2,2}^{-1}}} \sim \mathcal{N}(0, 1).$$

Combining this with the fact that

$$\frac{(n-p)s^2}{\sigma^2} \sim \chi_{n-p}^2,$$

where $s^2 = RSS/(n-p)$, we obtain the test statistic

$$\frac{\hat{\beta}_2}{s \sqrt{(X^T X)_{2,2}^{-1}}} \sim t_{n-p},$$

under H_0 . We perform the calculations in R:

```
n <- nrow(mammals)
p <- 3
beta.2 <- mod1$coefficients[3]
s <- sqrt(deviance(mod1)/(n-p))
X <- model.matrix( ~ log(body) + is.human, data = mammals)
XtX.inv <- solve(t(X) %*% X)

T.stat <- beta.2/(s*sqrt(XtX.inv[3,3]))
p.val <- pt(T.stat, n - p, lower.tail = F)
p.val

## is.human1
## 0.001777696
```

The calculated p-value is 0.0017777.

c)

We now consider the linear model with only two parameters, β_0 and β_1 . Let $Y_h = \beta_0 + \beta_1 x_h$ be the stochastic variable from which the log of the human brain mass is realized and $\hat{Y}_h = \hat{\beta}_0 + \hat{\beta}_1 x_h$ be the corresponding estimator. Then we can find the pivotal quantity

$$T = \frac{Y_h - \hat{Y}_h}{s \sqrt{1 + 1/n + \frac{(x_h - \bar{x})^2}{\sum_{i=1}^n (x_i - \bar{x})^2}}} \sim t_{n-2}.$$

We refer to the good old [subject-pages](#) (simple linear regression/prediction and prediction intervals in simple linear regression) for this result. Thus, we can find the one-sided prediction interval:

$$P(T \leq k) = 1 - \alpha \implies k = t_{n-2, \alpha}.$$

Rearranging, we arrive at

$$P\left(Y_h \leq t_{n-2, \alpha} \cdot s \sqrt{1 + 1/n + \frac{(x_h - \bar{x})^2}{\sum_{i=1}^n (x_i - \bar{x})^2}} + \hat{Y}_h\right) = 1 - \alpha$$

We denote the right hand side of the inequality above by U and calculate it with the observed values below

```
# HMMM trenegr ikke gjøre dette da egentlig?
x.h <- mammals$body[mammals$species == "Human"]
mammals.reduced <- mammals[mammals$species != "Human", ]
mod0.reduced <- lm(log(brain) ~ log(body), data = mammals.reduced)
summary(mod0.reduced)
pred.h <- predict(mod0.reduced, newdata = data.frame('body' = x.h))
s <- sqrt(deviance(mod0.reduced))
x.bar <- mean(mammals.reduced$body)
n <- nrow(mammals.reduced)
alpha = 0.05

U <- qt(1 - alpha, n) * s * sqrt(1 + 1/n + (x.h - x.bar)^2/sum((mammals.reduced$body - x.bar)^2) + pred
```

very uncertain on this one.

d) For a gamma-distributed random variable, the pdf takes the form

$$f(x | a, b) = \frac{b^a}{\Gamma(a)} x^{a-1} e^{-bx}.$$

Using the parametrization $\mu = \frac{a}{b}$ and $\nu = a$, we construct the GLM with a log-link as follows. Let the mammalian brain size given body size be given as

$$y_i \sim \text{Gamma}(\mu_i, \nu),$$

where

$$-\frac{1}{\mu_i} = \mathbf{x}_i^T \boldsymbol{\beta} =: \eta_i.$$

Next, we fit the model:

```
# log-link does not converge.
mod.glm <- glm(brain ~ body, family = Gamma(link = "inverse"), data = mammals)
summary(mod.glm)

##
## Call:
## glm(formula = brain ~ body, family = Gamma(link = "inverse"),
##      data = mammals)
##
## Deviance Residuals:
##      Min       1Q   Median       3Q      Max
## -3.4795  -2.3107  -1.6405  -0.0989   5.2752
##
## Coefficients:
##              Estimate Std. Error t value Pr(>|t|)
## (Intercept)  6.180e-03  2.036e-03   3.035  0.00355 **
## body        -9.088e-07  3.104e-07  -2.927  0.00482 **

##
##      Null deviance: 310.71  on 61  degrees of freedom
## Residual deviance: 250.89  on 60  degrees of freedom
## AIC: 692.09
```

```
##  
## Number of Fisher Scoring iterations: 8
```

e)

We want to test whether the following relationship holds:

$$Y = Y_0 M^{3/4},$$

where Y is the brain mass, Y_0 is a constant and M is the brain mass. Since this is equivalent to testing

$$\ln(Y) = \ln(Y_0) + \frac{3}{4} \ln(M),$$

we can, for the model in (b), simply perform the hypothesis test:

$$H_0 : \beta_1 = \frac{3}{4} \quad \text{vs.} \quad \beta_1 \neq \frac{3}{4}.$$

We follow the standard framework for a linear hypothesis test:

```
# Wald test:  
C <- matrix(c(0, 1, 0), nrow = 1)  
d <- 3/4  
r <- 1  
p <- 3  
n <- nrow(mammals)  
beta1 <- mod1$coefficients[2]  
s2 <- deviance(mod1)  
  
F.stat <- (beta1-3/4)^2/(s2*XtX.inv[2,2])  
p.val <- pf(F.stat, r, n - p, lower.tail = F)  
p.val
```

```
## log(body)  
## 0.9702783
```

How to use LRT test on linear hypothesis? very large p-value!

Problem 2

Assumptions

In this problem we apply ordinal multinomial regression to data from Norway Chess 2021.

```
df <- read.csv('data/Norway\ Chess\ 2021.csv')
```

The response variable y_i is the outcome of the i 'th match. This can be considered an ordered categorical variable

$$y_i = \begin{cases} 1 & , \text{ white win} \\ 2 & , \text{ draw} \\ 3 & , \text{ black win,} \end{cases}$$

which may depend on relative strength of different players, which player plays white and black and the type of game played. The response can be determined by an underlying latent variable u_i , given by

$$u_i = -\mathbf{x}_i^T \boldsymbol{\beta} + \epsilon_i,$$

where $\epsilon_i \stackrel{iid}{\sim} f$, where f is some standard distribution with cdf F . In this model, the event $y_i = r$ occurs if $\theta_{r-1} < u_i \leq \theta_r$ for some parameters $\{\theta_i\}_{i=0}^3$ satisfying

$$-\infty = \theta_0 < \theta_1 < \theta_2 < \theta_3 = \infty.$$

It follows that

$$P(y_i \leq r) = P(u_i \leq \theta_r) = P(\epsilon_i \leq \theta_r + \mathbf{x}_i^T \boldsymbol{\beta}) = F(\theta_r + \mathbf{x}_i^T \boldsymbol{\beta}),$$

so the probability of observing a particular outcome of the i 'th match becomes

$$\begin{aligned} \pi_{ir} = P(y_i = r) &= P(y_i \leq r) - P(y_i \leq r-1) \\ &= F(\theta_r + \mathbf{x}_i^T \boldsymbol{\beta}) - F(\theta_{r-1} + \mathbf{x}_i^T \boldsymbol{\beta}). \end{aligned}$$

This means that our model returns that white wins whenever $u_i \leq \theta_1$, draw if $\theta_1 < u_i \leq \theta_2$ and black win for $u_i > \theta_2$.

Models

Propositional odds model / Cumulative Logit

$$F(x) = \frac{e^x}{1 + e^x}, \quad \epsilon_i \sim \text{Logistic}(0, 1)$$

Cumulative Probit

$$F(x) = \Phi(x), \quad \epsilon_i \sim N(0, 1)$$

R

```
library(VGAM)
```

```
## Loading required package: stats4
```

```
## Loading required package: splines
```

```
fit <- vglm(y ~ factor(white) + factor(black),  
           family=cumulative(parallel = TRUE, link="logitlink"), data=df)
```

```
# P(u <= theta_1), P(u <= theta_2)  
p.less_or_equal <- plogis(predict(fit, df))
```

```
stats <- cbind('white'=df$white, 'black'=df$black,
              'P(white)'=round(p.less_or_equal[,1],2),
              'P(draw)'=round(p.less_or_equal[,2]-p.less_or_equal[,1],2),
              'P(black)'=round(1-p.less_or_equal[,2],2),
              'outcome'=c('white','draw','black')[df$y])
stats
```
